Simple Linear Regression Summary

Population Model

• The relationship between explanatory and response variable in the population is described by a line with intercept β_0 and slope β_1 , with normally distributed "errors" around the line

$$Y_i = \beta_0 + \beta_1 X_i + \varepsilon_i$$
$$\varepsilon_i \sim \text{Normal}(0, \sigma)$$

- Y_i is response variable value for observational unit number i (number of foals in i'th herd)
- X_i is explanatory variable value for observational unit number i (number of adults in i'th herd)
- β_0 and β_1 are **population parameters** we want to estimate

Plot line based on sample data

Fit linear regression model, print summary (Foals is response, Adults is explanatory)

```
lm_fit <- lm(Foals ~ Adults, data = horses)
summary(lm_fit)</pre>
```

```
bo, estimated intercept
                                                                 b1, estimated slope
## Call:
   lm(formula = Foals ~ Adults, data = horses)
                                                                 Standard Error for b1; this is an estimate
                                                                 of the variability in values of b1 we will
##
   Residuals:

```

Conditions for inference

Representative sample; No Outliers; Linear relationship; Independent observations; Normally distributed residuals; Equal variance of residuals

Equation of estimated line based on sample

Predicted Foals = $-1.578 + 0.154 \times Adults$

Interpretation of Estimated Intercept

The model predicts that if a herd contains 0 Adults, there will be -1.578 Foals born.

Interpretation of Estimated Slope

The model predicts that for each additional Adult in a herd of horses, an additional 0.154 Foals will be born.

Prediction for a Herd with 50 Adults

Predicted Foals = $-1.578 + 0.154 \times 50 = 6.122$.

The model predicts that a herd with 50 adults will have 6.122 foals.

Find and interpret a 95% confidence interval for β_1 (procedure similar for β_0)

Confidence Interval for β_1 : $b_1 \pm t^*SE(b_1)$, where:

- b_1 is estimate of slope based on this sample (from the R summary output)
- t^* is the critical value from a t distribution with n-2 degrees of freedom (from qt)
- $SE(b_1)$ is the standard error of b_1 (from the R summary output)

We are 95% confident that the slope of a line describing the relationship between the number of adults in a herd of horses and the number of foals born to that herd, in the population of all herds of horses, is between 0.13 and 0.18.

Conduct a hypothesis test with null hypothesis $\beta_1 = 0$

```
Test statistic: t = \frac{b_1 - \beta_1^{null}}{SE(b_1)} \sim t_{n-2}
(0.154 - 0)/0.0114
## [1] 13.51
2 * pt(-13.5, df = 36)
```

```
## [1] 1.175e-15
```

Note that the third column of the "Coefficients:" table on the previous page also has the test statistic for this test, and the fourth column has the p-value. The notation 1.175e-15 means $1.175*10^{-15} = 0.0000000000000001175$. Since the p-value is very small, we reject the null hypothesis. The data provide strong evidence that there is an association between the number of adults in a herd and the number of foals born to that herd.

Use the residual standard deviation to describe how good the model's predictions are.

About 95% of predictions from this model are within plus or minus 9.88 foals of the actual number of foals produced by a herd. (9.88 is two times the residual standard deviation from the R summary output.)

Use the R^2 value to describe how useful the model is (not that important, included for completeness)

The R^2 value for this regression is 0.835. This is close to 1, indicating that the points fall fairly close to the line. (Recall that R^2 is the square of the correlation between the explanatory and response variables.) This linear model accounts for about 83.5% of the variation in the response variable.
